Chapter 11: Thyristors

11. Thyristors

Thyristors are semiconductor devices characterized by 4-layers of alternating $p$- and $n$-material. Four-layer devices act as either open or closed switches; for this reason, they are mostly used in control applications.

Some thyristors and their symbols are:

(a) 4-layer diode  
(b) SCR  
(c) Diac  
(d) Triac  
(e) SCS
11. Thyristors

- The concept of 4-layer devices is usually shown as an equivalent circuit of a *pnp* and an *npn* transistor. Ideally, these devices would not conduct, but when forward biased, if there is sufficient leakage current in the upper *pnp* device, it can act as base current to the lower *npn* device causing it to conduct and bringing both transistors into saturation.

![Four layer device equivalent circuit](image)

11-1: The Four-Layer Diode

- The **4-layer diode** (or Shockley diode) is a type of thyristor that acts like an ordinary diode but conducts in the forward direction only after a certain anode to cathode voltage \( V_{AK} \) called the forward-breakover voltage, \( V_{BR(F)} \), is reached.

- The 4-layer diode has two leads, labeled the anode (A) and the cathode (K). The symbol reminds you that it acts like a diode.

- When a positive bias voltage is applied, the base-emitter junctions of and (pn junctions 1 and 3) are forward-biased, and the common base-collector junction (pn junction 2) is reverse-biased → at low level bias voltage → very little current \( I_A \) pass from A to K (can be neglected) → the diode is in off state (it has very high resistance).
11-1: The Four-Layer Diode: characteristic curve

- As bias voltage increases → $V_{AK}$ increases → leakage current ($I_{C1} = I_{B2}$) increases and hence anode current, $I_A$, increases very little until reaching the switching current $I_S$ at $V_{AK} = V_{BR(F)}$.
- The region at which the current $I_A$ is very little (can be neglected) is called the forward blocking region → the device has very high resistance → it is in its off state and acts as an open switch.
- When current reaches $I_S$, the forward voltage $V_{AK}$ suddenly decreases to a low value, and the 4-layer diode enters the forward-conduction region at holding current $I_{H}$ → the device has very low resistance → it is in the on state and acts as a closed switch.
- When the $I_A$ drops back below the holding value $I_{H}$, the device turns off and enters the forward blocking region. This is the only way to stop conduction.

Example: A 4-layer diode is biased in the forward-blocking region with $V_{AK} = 20$ V. If the anode current is 1 µA. Determine the resistance of the diode in the forward-blocking region.

$$R_{AK} = \frac{V_{AK}}{I_A} = \frac{20 \text{ V}}{1 \text{ µA}} = 20 \text{ MΩ}$$

Example: Determine the value of anode current in the diode D shown below when the device is on. $V_{BR(F)} = 10$ V. Assume the forward voltage drop of D is 0.9 V.

$$I_A = \frac{V_{bias} - V_D}{R_S} = \frac{20 - 0.9}{1kΩ} = 19.1mA$$
11-1: The Four-Layer Diode: Application

An application for the 4-layer diode is relaxation oscillator, shown in the circuit below.

- When the switch is closed, $C$ charges through $R$ → capacitor voltage and hence $V_{AK}$ increases until its voltage reaches the $V_{BR(F)}$ of the 4-layer diode → Diode switches on, and the capacitor rapidly discharges through the diode → $V_{AK}$ decrease → Discharging continues until the current through the diode falls below the holding value $I_H$. At this point, the diode switches back to the off state, and the capacitor begins to charge again. The result of this action is a voltage waveform across $C$ like that shown above.

11-2: The Silicon-Controlled Rectifier (SCR)

- The SCR had its roots in the 4-layer diode. By adding a gate connection, the SCR could be triggered into conduction. This improvement made a much more useful device than the 4-layer diode.

- The SCR equivalent circuit shows that the gate current is applied to the third p-region of the device providing a current pulse (a trigger) to the base of $Q_2$.
- SCR can be turned on by exceeding the forward breakover voltage or by gate current.
11-2: The Silicon-Controlled Rectifier (SCR)

- At low level $V_{AK}$ when $I_G = 0 \Rightarrow$ the SCR is off and no forward current will pass.
- When a positive pulse of current (trigger) is applied to the gate, both transistors turn on (there must $V_A > V_K$) $\Rightarrow$ $I_{B2}$ turns on $Q_2$, providing a path for $I_{B1}$ into the $Q_2$ collector, thus turning on $Q_1$.
  
  The collector current of $Q_1$ provides additional base current $I_{B2}$ for $Q_2$ so that $Q_2$ stays in conduction after the trigger pulse is removed from the gate.

---

11-2: The Silicon-Controlled Rectifier (SCR): Characteristic Curve

- At $I_G = 0$, the characteristic curve it typically like the four-layer Diode.
- as $I_G$ is increased above 0 V $\Rightarrow$ $V_{BF(F)}$ decreases $\Rightarrow$ we can have the SCR turns on at a very low $V_{AK}$ as $I_G$ is increased to suitable value $\Rightarrow$ the $I_G$ controlled the value $V_{BR(F)}$ required for turn-on.
11-2: The Silicon-Controlled Rectifier (SCR): Turning the SCR Off

- Like the 4-layer diode, the SCR will conduct as long as forward current exceeds $I_H$. There are two ways to drop the SCR out of conduction: anode current interruption and forced commutation.

  1) Anode current can be interrupted by breaking the anode current path (shown here) or providing a path around the SCR → dropping the anode voltage to the point that $I_A < I_H$.

  2) Force commutation uses an external circuit (like the shown) to momentarily forcing current through the SCR in direction opposite to the direction of forward conduction current $I_F$.

- SCRs are commonly used in ac circuits, which forces the SCR out of conduction when the ac reverses.

11-3: SCR Applications

The SCR is used in many applications, including motor controls, time-delay circuits, heater controls, phase controls, relay controls, and sawtooth generators.

- On-Off Control of Current

The figure shows an SCR circuit that permits current to be switched to a load by the momentary closure of switch SW1 and removed from the load by the momentary closure of switch SW2.

Example:

Determine the gate trigger current and the anode current when the switch, SW1, is momentarily closed in Figure 11-16. Assume $V_{AK} = 0.2 \text{ V}$, $V_{GK} = 0.7 \text{ V}$, and $I_H = 5 \text{ mA}$.

$$I_G = \frac{V_{TRIG} - V_{GK}}{R_G} = \frac{3 \text{ V} - 0.7 \text{ V}}{5.6 \text{ k}\Omega} = 410 \mu\text{A}$$

$$I_A = \frac{V_A - V_{AK}}{R_A} = \frac{15 \text{ V} - 0.2 \text{ V}}{33 \text{ } \Omega} = 448 \text{ mA}$$
A common application of SCRs is in the control of ac power for different applications like lamp dimmer, electric heaters, and electric motors.

A half-wave, variable-resistance, phase-control circuit is shown in figure above; $R_L$ represents the resistance of the load. Resistor $R_1$ limits the current, and potentiometer $R_2$ sets the trigger level for the SCR.

The SCR conduct at positive half cycle (because $V_A>V_K$). At negative half cycle $\Rightarrow$ The SCR does not conduct (because $V_A<V_K$).

By adjusting $R_2$, the SCR can be made to trigger at any point on the positive half-cycle of the ac waveform between 0° and 90°.

In figure (a) $R_2$ is adjusted at highest $V_{GK} \Rightarrow I_G$ is max. $\Rightarrow$ the SCR is conduct near the beginning of the cycle $\Rightarrow$ RL is conducting for approximately 180° $\Rightarrow$ max power delivered to $R_L$.

In figure (b) $R_2$ is adjusted at intermediate $V_{GK} \Rightarrow I_G$ is less than in (a) $\Rightarrow$ the SCR is conduct near the peak of the cycle $\Rightarrow$ $R_L$ is conducting for approximately 90° $\Rightarrow$ less power delivered to $R_L$.

In figure (c) $R_2$ is adjusted at $V_{GK}$ between that in (a) and (b) $\Rightarrow I_G$ is between that in (a) and (b) $\Rightarrow$ the SCR is conduct midway between (a) and (b) $\Rightarrow$ $R_L$ is conducting for approximately 45°.
11-3: SCR Applications

- Backup Lighting for Power Interruptions

The figure shows a full-wave rectifier used for providing power to a low-voltage lamp. As long as the ac power is available, the battery charges through diode $R_1$ and $D_3$. Also $C$ is charged to voltage higher than anode $V_K > V_A = +6V$ of the battery.

When there is an interruption of ac power, the capacitor discharges through $R_1$, $D_3$, and $R_3$ $V_K < V_A$ or gate SCR begins to conduct Current from the battery is through the SCR and lamp lamp maintaining illumination.

11-3: SCR Applications

- Sawtooth generator

The circuit shown is used to produce the sawtooth wave.

The time constant is set by $R_1$ and $C_1$, and the voltage at which the SCR triggers on is determined by the variable voltage-divider formed by $R_2$ and $R_3$.

When the switch is closed, the capacitor begins charging increasing the $V_{AK}$ at $V_{BR(F)}$, the SCR turns on. When the SCR turns on, the capacitor quickly discharges through it $V_{AK}$ decrease the anode current then decreases below the holding value, causing the SCR to turn off. As soon as the SCR is off, the capacitor starts charging again and the cycle is repeated.

By adjusting the potentiometer, the frequency of the sawtooth waveform can be changed.
11-4: The Diac and Triac

The diac and the triac are types of thyristors that can conduct current in both directions (bilateral). The difference between the two devices is that a diac has two terminals, while a triac has a third terminal, which is the gate for triggering.

**The Diac**

- The diac acts like two back-to-back 4-layer diodes. It can conduct current in either direction. It is constructed of two back to back *pn*-*pn* as shown. Because it is bidirectional, the terminals are equivalent and labeled A₁ and A₂.
- The diac conducts current after the breakdown voltage is reached with either polarity across the two terminals, as shown in the characteristic curve. At break points, the diac goes into avalanche conduction, creating a forward (I_F) or reverse (I_R) current. The diac remains in conduction as long as the current is above the holding current, I_H.

**The Triac**

- The equivalent circuit of a triac consists of four transistors arranged as shown in Figure (a).
- When the diac is biased as in Figure (b), the *pn*-*pn* structure from A₁ to A₂ provides the same operation as was described for the 4-layer diode. In the equivalent circuit, Q₁ and Q₂ are forward-biased, and Q₃ and Q₄ are reverse-biased → device work in upper portion of the characteristic curve.
- When the diac is biased as in Figure (b), the *pn*-*pn* structure from A₂ to A₁ → Q₃ and Q₄ are forward-biased, and Q₁ and Q₁ are reverse-biased → device work in lower portion of the characteristic curve.
11-4: The Diac and Triac

The Triac

- The Triac acts like a diac with a gate terminal used to trigger the device on so that it conducts at lower break voltage than in the diac.

- Basically, a triac can be thought of simply as two SCRs connected in parallel and in opposite directions with a common gate terminal; it conducts current in both direction when triggered on, depending on the polarity of the voltage across \( A_1 \) and \( A_2 \).

- The characteristic curve shows that the breakover potential decreases as the gate current increases (like the SCR). The triac turns off when the anode current drops below \( I_{th} \).

11-4: The Diac and Triac

The Triac

- The mechanism of conduction for a triac in both direction is shown on equivalent circuit for two shown voltage polarities.

The conduction of current in both direction for the diac is very similar to the conduction of current in the SCR.
11-4: The Diac and Triac

The Triac: An application

- Triacs are used for control of ac power by the method of phase control as shown. It is used in applications like electric range heating controls, light dimmers, and small motors.

- Phase control using a triac is illustrated in Figure (a).

During the positive half-cycle, $D_1$ conducts $\Rightarrow G$ and $A_1$ are +ve with respect to $A_2$. The value of $R_1$ sets the point on the positive half-cycle at which the triac triggers.

During –ve half cycle, $D_2$ conducts $\Rightarrow G$ and $A_2$ are +ve with respect to $A_1$. Triac conducts during –ve cycle at a trigger point set by $R_1$.

11-5: The Silicon controlled switch (SCS)

- The SCS is similar to an SCR but with two gate (cathod gate, $G_K$, and Anode gate, $G_A$) that are used to trigger the device on and off. SCS is also used in similar application for SCR, but with faster turn off.

Turning on SCS: +ve pulse on $G_K$ drive $Q_2$ into conduction $\Rightarrow$ it provide path for $Q_1$ to switch on (like SCR). Also, -ve pulse on $G_A$ drive $Q_1$ into conduction $\Rightarrow$ provide current for $Q_2$ base $\Rightarrow Q_2$ switch on.

Turning off SCS: +ve pulse on $G_A$ makes EB junction of $Q_1$ reverse bias $\Rightarrow Q_1$ turns off $\Rightarrow Q_2$ also cut off.

Also, -ve pulse on $G_K$ makes BE of $Q_2$ reverse bias $\Rightarrow Q_2$ turns off and hence $Q_1$ will become off.
